**Abstract:** In the present study, the *Myristica fragrans* shells (MFS) was used as low-cost bio adsorbent for the removal of Rose Bengal (RB) dye from aqueous solutions. The characteristics of MFS powder were studied before and after adsorption using different techniques such as Fourier transform Infrared spectroscopy (FTIR), Thermal Gravimetric Analysis (TGA), BET and BJH surface area analysis, Atomic Force Microscopy (AFM) and Scanning Electron Microscopy (SEM). Batch adsorption was adopted to evaluate the effect of various parameters on the removal of RB such as; time of contact (5–75 min), initial dye concentration (10–50 mg L⁻¹), adsorbent dose (0.1–1.7 g L⁻¹) and pH (3–12). The results revealed that the coverage of MFS surface by RB molecules involved the formation of ester bond (esterification), and the pore diameter decreased from 190.55 to 2.43 nm when adsorption of RB onto MFS surface occurred. Experimental adsorption data were modelled using isotherm models including Langmuir, Freundlich, and Temkin. Temkin isotherm demonstrated to be the best isothermal model, and the results indicate that the adsorption of Rose Bengal on MFS surface follows pseudo second-order kinetics model. The adsorption of dye at different pH media showed that the esterification process was more preferred in acidic solution.

**INTRODUCTION**

The spread of huge quantities of toxic contaminants in surface water and groundwater has a potential effect on human health [1]. There are numerous toxic contaminants found in wastewater such as, heavy metals, Radiological contaminants, synthetic organic and inorganic contaminants (i.e., dyes, pesticides, phenolic compounds, petrochemicals, pharmaceuticals, etc.) [2-5]. Water contaminated with untreated dyes can cause a serious environmental impedance to aquatic and human life [6]. Many type of dyes are non-biodegradable in nature and under anaerobic conditions might decompose into carcinogenic aromatic amines [7]. Rose Bengal dye is a fluorescent compound that is widely used in early-stage diagnosis of keratoconjunctivitis sicca (KCS) in vivo effect on the human corneal epithelium [8]. Xanthene dyes have toxicity which cause a series of risks on the human health especially by inhibition of human drug-metabolizing enzymes and can cause eye redness and itching [9].

Among waste water treatments such as, ozonation, photochemical degradation, reverse osmosis, membrane separation and coagulation, the adsorption process is the most effective, low cost and most easily available method that has been successfully employed for removing pollutants from the waste water [10]. Kaur et al. used UV light for the degradation of dyes and found that under UV light, very small degradation was observed [11].
Numerous studies have focused on the utilization of natural materials, such as egg shells [12], bean peels [13], and marble waste [14], as adsorbents for the removal of pollutants from aqueous mediums. Activated carbon is the most widely used adsorbent for the removal of dyes from waste water effluents, due to its high capacity for organic compounds, however its application is still limited due to the high cost [15].

*Myristica fragrans* shell (MFS) is a waste product of the nutmeg industry. In the present study, MFS have been utilized for the removal of toxic materials from water. The adsorption dye on MFS surface was evaluated using different variable parameters. In addition, techniques such as AFM, FESEM, FTIR, BET/BJH, and TGA/DTA were used to elucidate the effect of dye adsorption on the surface characteristics of the adsorbent.

### EXPERIMENTAL SECTION

#### Materials

Hydrochloric acid (HCl, 37%), and Sodium hydroxide (NaOH, 99.5%) were purchased from BDH. Rose Bengal (C₂₀H₂Na₂O₅I₄Cl₄, Dye content 95%) was purchased from Sigma-Aldrich. The chemical structure of RB dye is present in Fig. 1. It is well-known that RB possess high solubility in water, and its λ max = 549 nm.

#### Procedure

**Preparation of adsorbent**

The MFS powder was obtained from MFS waste, and was ground and sieved through 150 mesh sieve. After sieving, the collected fine powder was washed several times with distilled water to remove contaminants and soluble materials. The clean powder was then dried in an oven at 100 °C for 4 h and it was placed in a desiccator to keep dry until use.

**Batch mode adsorption studies**

The adsorption studies were done by batch experiments which aimed to determine the adsorption parameters such as contact time initial dye concentration, initial pH solution, and adsorbent dose by changing one parameter under study, while other parameters were set in a fixed value. Different concentrations (10, 20, 30, and 40 ppm) were obtained by successive dilution of a dye stock solution of 50 ppm. Five conical flasks (250 mL) containing 100 mL of dye solution and 1.7 g of MFS surface were stirred on a shaker water bath at the rate of 120 rpm for the required time of equilibrium. The equilibrium concentration of the solution were determined by using UV-Visible technique (Shimadzu, UV-1650PC) at λ max (nm), after separation of the supernatant. The quantity and the removal percentage of the adsorbed dye on the adsorbent at the equilibrium time (qₑ) were calculated using Eq. (1) and (2) respectively.

\[
qₑ = \frac{V(C₀ - Cₑ)}{m}
\]  
\[
qₑ = \frac{V(C₀ - Cₑ)}{m}
\]

where \(C₀\) and \(Cₑ\) are RB concentrations (ppm) at the initial and the equilibrium time, respectively. \(qₑ\) (mg g⁻¹), is the amount of RB adsorbed on a fixed adsorbent mass (g) at the time of equilibrium. \(V\) is the volume (in L) of the initial RB solution.

#### Characterization

MFS before and after dye adsorption were characterized by Shimadzu 8400S FTIR with wavenumber range of 400–4000 cm⁻¹ at a scan resolution of 4 cm⁻¹. Field emission scanning electron microscope (FESEM, MIRA3 TESCAN) with accelerating voltage 10 kV and angstrom AFM (SPM AA3000) were used to study the surface morphology of MFS surface. Under nitrogen atmosphere at 20 mL/min gas flow rate and heating at the rate of 20 min⁻¹, the thermogravimetric analysis (TGA) was done by Perkin Elmer (TGA 4000). Surface area and pore analysis were carried out using Nova
Characterization of MFS Before and After Adsorption

**Functional groups**

The FTIR spectrum of MFS before and after dye adsorption are shown in Fig. 2, in which the MFS spectrum shows a broad peak centered at 3385 cm⁻¹ due to the intramolecular and intermolecular hydrogen bonding of the –OH, –NH₂ groups. Stretching and bending vibration of the C-H band is shown in the MFS FTIR spectrum at 2930, 2884, 1427, 1381, and 1321 cm⁻¹. A strong peak located at 1653 cm⁻¹ is indexed to the carbonyl group (C=O) stretching vibration, while a weak band with multiple peaks at 1040, 1123, 1238 and 1267 cm⁻¹ is assigned to alcohols, carboxylic acids and ethers (1000–1320 cm⁻¹ attributed to C–O stretch) [16]. As reported in the literatures, the carbonyl stretching vibration of free RB is shown at 1614 cm⁻¹ [17]. The FT-IR spectra of MFS after dye adsorption shows the carbonyl frequency at wavenumber, 1734 cm⁻¹, which confirms that the dye has been covalently attached to the MFS, and also the formation of an ester bond between alcoholic and carboxylic groups [18]. In addition, a broadband of 3385 cm⁻¹ was shifted to higher wavenumber of 3419 cm⁻¹ due to the weakness of the MFS intermolecular hydrogen bonding between its molecules after adsorption of the RB dye.

**Surface topology**

AFM image of the MFS before adsorption is depicted in Fig. 3(a). As AFM technique reveals, the morphology of MFS to be a porous surface with roughness average of about 5.35 nm and surface skewness of about -0.234. Fig. 3(b) depicts the AFM images of the
MFS after adsorption of the dye. Dye adsorption causes the lowering of porosity of the MFS surface and increasing of thickness in comparison with the state before adsorption. The AFM rough analysis of the MFS negative Skewness is due to the number of surface valleys that were higher than the peaks [19], and after adsorption of the dye, the skewness value became positive due to the decrease in the number of valleys and enclosed by dye molecules [20].

**Surface morphology**

The surface morphology of MFS before and after adsorption were examined by scanning electron microscopy, as presented in Fig. 4. MFS image shows irregular particle shapes with large scale of pores. After dye adsorption, the surface of MFS was smooth and had no sharp edges with small scale pores in compression with MFS, and the coated surface clearly shows that dye particles were accumulated on the surface of MFS.

**Surface area and porosity**

Fig. 5 shows BET adsorption-desorption isotherms of MFS before and after adsorption. The obtained surface properties such as the BET surface area, and the BJH pore volumes are summarized in Table 1. According to
the classification proposed by (IUPAC), the isotherms of MFS can be classified as type III, where the adsorbate uptake increases exponentially due to the weak interaction between the adsorbate (N₂ gas) and the adsorbent and to the microporous nature [21]. In reference to literature, the hysteresis loops of MFS is H3 type which is indexed to the presence of non-rigid aggregates of sheet-like particles or assemblages of slit-shaped pores [22]. The surface area of MFS was 4.4 m²/g, whereas MFS after the adsorption of RB have schematically undefined curves and cannot be applied to the BET sorption isotherm models which may be due to lower surface area of the sample. This results complies with their morphology (Fig. 3 and Fig. 4). The pore volume and pore diameter of the MFS surface decreased with the adsorption of molecules due to the filling of the pore voids with the dye molecules. Results show that the pore volume decreased by 71.29%, and the average diameter decreased from 190.55 to 2.43 nm due to the dye adsorption on the MFS surface.

### Thermal Analysis

The Thermogravimetric analysis results of MFS before and after dye adsorption are shown in Fig. 6. TGA and DTA curves of MFS show three steps in weight loss (Table 2): The first stage of weight loss in the temperature range of 30 to 200 °C represents the removal of physically adsorbed water [23]. The second step of weight loss in the temperature range of 200–500 °C can be attributed to the organic breakdown of MFS biomass and the loss of the organic volatile compounds. The third

#### Table 2. TGA/DTA data of MFS and MFS-RB before and after adsorption of RB
stage occurred in the range of temperature of 500–800 °C which corresponds to the carbonization of the material and formation of charcoal [24]. The charcoal residues after MFS and MFS-RB were heated to 800 °C, were 6.313 and 4.878%, respectively. The decrease in the residues percentage (1.435%) of MFS-RB was due to the pyrolysis of the RB dye in the third stage of the TGA analysis, in accordance to the data obtained from the lookchem supplier web, in which the RB dye boiling point is 741.8 °C at 760 mmHg [25].

Effect of Contact Time and Adsorption Kinetics

The time-dependent behavior of the dye adsorption was investigated by varying the contact time between the RB dye and the MFS in the range of 5–75 min. The concentrations of the dye was kept at 50 ppm and MFS mass was kept at 1.7 g. The result for the removal of RB versus contact time is presented in Fig. 7. More than 80% of dye was adsorbed at contact time of 10 min and adsorption increased with time reaching to a maximum value in 65 min and afterwards remained constant. In context, the adsorption equilibrium time of the RB dye was 65 min for MFS.

To investigate the kinetic mechanism of adsorption, the experimental data was fitted to the pseudo-first order, the pseudo-second order, and intraparticle diffusion models. The three models are generally expressed as follows:

Pseudo-first order model (linear form) [26]:
\[ \ln(q_e - q_t) = \ln(q_e) - k_1t \]  
(3)

Pseudo-second order model (linear form) [27]:
\[ \frac{t}{q_t} = \frac{1}{k_2q_e^2} + \frac{1}{q_e} \]  
(4)

Intraparticle diffusion model (linear form) [28]:
\[ q_t = k_D t^{0.5} + I \]  
(5)

where \( q_e \) and \( q_t \) = the amount of RB adsorbed at equilibrium and at t time, respectively (mg·g\(^{-1}\)), \( k_1 \) = the overall rate constant of pseudo-first order kinetics (min\(^{-1}\) mg g\(^{-1}\)), \( k_2 \) = the rate constant of pseudo-second order (mg g\(^{-1}\) min\(^{-1}\)), \( k_D \) = the rate constant of intraparticle diffusion (mg g\(^{-1}\) min\(^{-1}\)\(^{1/2}\)) and I = the intercept reflecting the thickness of boundary layer.

Fig. 7(b), (c) and (d) show the kinetic models of RB adsorption on the MFS surface. The adsorption kinetic pseudo-second order was more linear with \( R^2 \) of 0.999.

compared to the pseudo-first order plot and intraparticle diffusion plot (see Table 3). In addition, the value of ($q_{e, cal}$) in this model is closer and more accurate than the other models. This result confirmed that the adsorption process followed the pseudo-second order which assumed that chemisorption occurred, which involved chemical reactions between adsorbent and adsorbate [29].

**Adsorption Isotherm Studies**

Fig. 8(a) shows the adsorption isotherm of RB dye. Referring to the theoretical basis of Giles’s classification of adsorption isotherms, the isotherm of RB was of S-type, which assumed that the adsorbent is possibly mesoporous or is not porous and has a high energy of adsorption. The reaction between adsorbent and adsorbate can be determined by isotherm study. There are different isotherm equations available for studying the experimental sorption equilibrium data. However, the most common types of isotherms are the Langmuir, Temkin and Freundlich models:

- **Langmuir isotherm model** [30]:
  \[ \frac{q_e}{C_e} = \frac{1}{q_m K_a} + \frac{1}{q_m} \]

- **Freundlich isotherm model** [31]:
  \[ \log q_e = \log K_f + \frac{1}{n} \log C_e \]

- **Temkin isotherm model** [32]:
  \[ q_e = B_1 \ln K_T + B_1 \ln C_e \]

where $q_e$ is the amount of RB adsorbed (mg/g) at $C_e$ (equilibrium concentration), $q_m$ and $k_a$ are Langmuir constants related to adsorption efficiency and energy of adsorption, respectively. $K_f$ and $1/n$ are constants incorporating the factors affecting the adsorption capacity and intensity of adsorption, respectively. $\beta = RT/b$, $(T)$ is the thermodynamic temperature in Kelvin degrees and $(R)$ is the universal gas constant, 8.314 J mol$^{-1}$ K$^{-1}$. The constant $(b)$ is identified as the adsorption heat.

Fig. 8(b), (c) and (d) show the isotherm models of RB adsorption on the MFS surface. It is clearly seen that plot of Temkin isotherm is more linear with \( R^2 \) of 0.980 in comparison to other models of isotherms (show Table 4). Temkin isotherm contains a factor that explicitly taking into the account of adsorbent-adsorbate interactions and assumes that heat of adsorption of all molecules in the layer would decrease linearly rather than in logarithmic manner with the coverage [33].

**Adsorbent dosage**

To optimize the MFS dosage, the effect of adsorption amount on removal of RB dye was carried out. Fig. 9(a) shows the dependence of MFS mass on RB adsorption percentage. It was observed that RB removal increased with the increase of the amount of MFS adsorbent. The maximum removal of dyes was observed with the dosage (1.7 g) used for all subsequence experiments the results are shown in Fig. 9(a).

**Initial pH effect**

Different pH values (3, 4, 9 and 12) were used to study the pH effect on adsorption of RB dye onto MFS. Initial pH dye solutions were adjusted by using 0.1 N of HCl and 0.1 N of NaOH. Fig. 9(b) depicts the relationship between RB removal percentages with the initial pH values of the RB solutions. It is clearly seen that the amount of dyes removed at pH 3 produced a large adsorbate quantity. The dye removal was expected to increase due to the esterification process that was found to be more favorable at acidic solution (pH < 3). The IR spectral lines proves the occurrence of esterification by the appearance of a peak at 1734 cm\(^{-1}\).

**Effect of Temperature**

The effect of temperature on RB adsorption on MFS surface at (35–55) °C is shown in Fig. 10(a). It shows that the adsorption process decreased with the rise in temperature due to the reduced attractive forces between the RB molecules and MFS [34]. The enthalpy variation (\( \Delta H \)), and other thermodynamic parameters such as free energy variation (\( \Delta G \)), and entropy variation (\( \Delta S \)) follows the following equations [35]:

\[
\ln X_m = -\frac{\Delta H}{RT} + C
\]

\[
\Delta G = -RT \ln K
\]

\[
\Delta G = \Delta H - T \Delta S
\]

where \( X_m \) is the maximum amount adsorbed \( (q_m) \) at a certain value of concentration equilibrium \( (C_o) \), and \( (K) \) is the distribution coefficient. The value of \( \Delta H^o \) was determined from the slope value of the straight line of plotting \( \ln X_m \) versus \( 1/T \) (Fig. 10(b)). The negative value of enthalpy \( \Delta H = -42.447 \text{ kJ/mol} \) and entropy \( \Delta S = -147 \text{ J mol}^{-1} \text{ K}^{-1} \), confirmed the exothermic process and that the RB molecules have ordered arrangement on MFS surface [36]. On the other hand, the positive value of free energy \( \Delta G = +3065 \text{ kJ/mol} \) indicated that the adsorption process is unfavorable.

![Fig 9. (a) Effect of adsorbent dosage and, (b) pH effect on adsorption of RB](image-url)
process was thermodynamically non-spontaneous [35]. The value of ∆H was more than 40 kJ/mol which indicates that the uptake of RB dye onto MFS could be attributed to a chemisorption process [37].

■ CONCLUSION

In the present study, we examined the adsorption of Rose Bengal onto Myristica fragrans shells. We strongly suggest that chemisorption by ester bond formation between adsorbate and adsorbent occurred. This result was confirmed by FTIR and adsorption study.
