Abstract: The first copper-doped titanium-based amine-dicarboxylate metal-organic framework was synthesized by the solvothermal approach in this article, with a Cu2+/Ti4+ ratio of 0.15 (15% Cu/Ti-MOFs). X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR), Raman spectra, N2 adsorption-desorption studies, and UV-Vis diffuse reflectance spectroscopy (UV-Vis DRS) were all used to identify the crystalline and properties of the semiconductors. The rate constants of 15% Cu/Ti-MOFs to degrade Rhodamine B (RhB) were roughly two times higher than NH2-Ti-MOFs. Furthermore, 15% Cu/Ti-MOFs photocatalysts remained stable after three cycles. The trapping test revealed that the principal active species in the degradation performance were hydroxyl radicals and holes.

Keywords: bimetallic Cu/Ti-MOFs; photocatalytic; degradation; Rhodamine B; kinetic

INTRODUCTION

Organic dyes have been widely used in the textile and print industries. However, because these compounds are toxic, non-biodegradable, and potentially carcinogenic, their release into the water supply could endanger humans and the environment [1]. Rhodamine B (RhB) is an example of a highly toxic dye [2]. Nonetheless, RhB is still used as a fluorescent dye for staining in biology, sometimes in conjunction with auramine O to form the auramine-rhodamine stain [3]. As a result, there is a pressing need to design an effective dye wastewater treatment process.

Metal-organic frameworks (MOFs) have many possible uses due to their huge surface areas, homogeneous yet configurable cavities, and tailorable physicochemical features [4-6]. Gas adsorption and storage [7], separation [8], drug delivery [9], and catalysis [10] are a few typical examples. In addition, the cost-effective photocatalysis process has gained popularity due to its advantages, such as biodegradable and non-toxic end products.

Recently, the photoactive, crystalline, and highly porous titanium-oriented MOFs NH2-MIL-125(Ti) exhibiting Ti8O8(OH)4(O2CC6H3(NH2)CO2)6 have
received much attention in the photocatalysis domain [11-13]. NH$_2$-MIL-125(Ti) is crystal titanium-based amine-dicarboxylate with excellent absorbance, encapsulation potential, and stability [14]. This material is also embellished with numerous inactive Ti sites. However, due to its exclusive activation in the UV light area and quick charge recombination, its employment in photocatalytic platforms is limited, resulting in poor photocatalytic efficiency [15].

When suitable energy light strikes the photocatalyst, the generated electron-hole pair participates in the reaction [16]. Electron-hole pair recombination must be avoided to be so large to promote photocatalysis. The photocatalytic activity of MOFs has been improved using various techniques, including coupling with noble metals [17-18] and forming heterojunctions with other semiconductors [19-20]. Furthermore, metal doping is a potential method for regulating the electronic structure and improving photocatalytic activity. For example, Hong Liu et al. used an in situ doping approach to create new copper-doped titanium-based amine-functionalized metal-organic frameworks (Cu-NH$_2$-MIL-125(Ti)).

In this work, the photocatalytic activity of produced samples was demonstrated through the degradation of methyl orange (MO) and phenol under visible light [21]. In 2019, Gómez-Avilés et al. synthesized mixed Ti-Zr-MOFs and tested them as photocatalysts under solar-simulated radiation using acetaminophen (ACE) as a target pollutant [22]. However, a full comprehensive determination of the structure and photocatalysis mechanism of these materials remains challenging. The photocatalytic performance of bimetallics strongly depends on their composition and microstructures. Herein, the scope for further investigation into the role played by Cu$^{2+}$ in NH$_2$-MIL-125(Ti), which is also rare recently.

This article reports a simple method of synthesizing NH$_2$-Ti-MOFs and bimetallic 15% Cu/Ti-MOFs using the solvothermal method. The bare Ti-MOFs were prepared to compare with 15% Cu/Ti-MOFs to highlight the advantage of transition metal-based on its superior optical performance. Moreover, Cu$^{2+}$ was also supposed to play a part in the structural adjustment of NH$_2$-Ti-MOFs.

### EXPERIMENTAL SECTION

#### Materials

Titanium (IV) isopropoxide (TiOCH(CH$_3$)$_2$), 2-amino terephthalic acid (NH$_2$-BDC) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA), copper(II) chloride (CuCl$_2$) were obtained from Fisher Scientific (Fair Long, NJ, USA), N-dimethylformamide (DMF, 99.5%) and methanol (CH$_3$OH) were obtained from Xilong Chemical Co., Ltd (China).

#### Instrumentation

The catalysts were identified using the powder X-ray diffraction (PXRD) technique, which used a 600 XRD diffractometer (Shimadzu, Japan) with Cu Kα radiation (λ = 1.5418) at a scan rate of 0.020°/s in the 5–40 range of the 2-theta range. Raman spectroscopy was performed using a HORIBA Jobin Yvon spectrometer (Horiba Scientific, Japan) with a wavenumber range of 100–1000 cm$^{-1}$ (633 nm of the laser beam). FTIR spectroscopy was performed on the sample KBr pellets using a Jasco-4700 FTIR Spectrometric Analyzer (Japan). Nitrogen physisorption was used to investigate the BET and pore size distributions using a Micromeritics Tristar 3000 analyzer. The UV-vis DRS was measured at wavelengths ranging from 200 to 800 nm (UV-2450, Shimadzu, Japan).

#### Procedure

**Preparation of NH$_2$-Ti-MOFs and 15% Cu/Ti-MOFs**

NH$_2$-Ti-MOFs were synthesized via the report of Hanna et al. (2020) [23]. Briefly, 0.504 g 2-amino-1,4-benzene dicarboxylate (BDC–NH$_2$) was dissolved in 12.1 mL N,N-dimethylformamide (DMF). 1.4 mL methanol was added to the mixture and magnetically stirred at room temperature for 30 min. Next, 0.26 mL of titanium isopropoxide was added to the mixture, with continued stirring until homogenous, and later added with 20 mg of CTAB surfactant. Then, the reaction mixture was transferred to a heat-resistant 100 mL Teflon and placed in a closed convection heat apparatus at 150 °C for 24 h. The product was then cooled and refluxed overnight at 80 °C to remove BDC-NH$_2$ from the pores. Next, the obtained material was centrifuged,
washed several times with DMF and methanol, and vacuum dried overnight at 150 °C. The mixed Cu/Ti-MOFs were synthesized according to the copper molar percentage of the ratio Cu²⁺/Ti⁴⁺ of 0.15.

**Photocatalytic test**

The ability of NH₂-Ti−MOFs and 15% Cu/Ti-MOFs samples to degrade RhB with the help of H₂O₂ and the presence of visible light demonstrates their photocatalytic activity. The catalyst (5 mg) was combined with RhB (100 mL, 3 × 10⁻⁵ M) and 1 mL H₂O₂ (2 mM) in a 250 mL double-layer beaker. Before photocatalytic degradation, the suspensions were magnetically stirred for 1 h without light to achieve equilibrium adsorption and desorption. Herein, 4 mL of samples were removed during the photodegradation process and centrifuged at 6000 rpm at regular intervals for 10 min to separate the solid material. An Agilent Cary (USA) was used to measure dye concentration and absorption.

**Trapping test**

The RhB photodegradation of 15% Cu/Ti−MOFs was conducted using different scavenger compounds to obtain in-depth knowledge about the photocatalytic reaction mechanism. O₂•⁻, HO• and h⁺ scavengers were inhibited by p-benzoquinone (BQ), tert-butanol (TBA), and EDTA−2Na, respectively. The concentrations of TBA and EDTA were fixed at 1 mM, while the concentration of BQ was fixed at 1 μM.

**RESULTS AND DISCUSSION**

**Characterization of NH₂-Ti−MOFs and 15% Cu/Ti−MOFs**

The XRD patterns of NH₂-Ti-MOFs and 15% Cu/Ti-MOFs are shown in Fig. 1(a). The diffraction peak intensity at 2θ = 6.8° is attributed to the NH₂-Ti-MOFs bare [24-25]. Noticeably, the diffraction peaks are slightly moved to lower angles when doping with ionic Cu²⁺ into the titanium framework. This can be explained based on the difference of the ionic radius of Cu²⁺ and Ti⁴⁺ which are 0.72 and 0.68 Å, respectively [21]. The slight decrease observed is probably due to the thermal treatment following metal deposition [26]. However, the modification of ion Cu²⁺ had not changed the crystalline phase of NH₂-Ti-MOFs.

Therefore, the formation of 15% Cu/Ti-MOFs was further confirmed.

Raman spectroscopy was used to investigate the bonding vibration of Ti-MOFs and 15% Cu/Ti-MOFs bimetallic materials (Fig. 1(b)). All of the spectra had the same characteristic peaks. The relatively strong bands observed at 325 nm at 546, 640, 1145, and 1620 cm⁻¹ characterize NH₂-MIL-125(Ti) materials [27]. The type of framework of titanium is responsible for the resonance-enhanced Raman band at 703 cm⁻¹. The N–H bond of the organic bridge is represented in the band at 1620 cm⁻¹ [28]. The appearance of a band of symmetrical bending and elongation at 546 cm⁻¹ is typical for octahedral Ti−O−Ti−O [29].

The nitrogen adsorption/desorption analyses at 77 K were used to explore the specific surface areas and porosity of MOF materials. As displayed in Fig. 2, all the samples exhibit the typical isotherms of IV, indicative of the presence of a large number of micropores with some small contribution of mesoporosity and high surface area values. The Brunauer-Emmett-Teller (BET) surface areas of the as-prepared NH₂-Ti-MOFs and 15% Cu/Ti-MOFs were 970.23 and 1157.41 m²/g, respectively. Therefore, as in the case of the crystalline structure, metal cluster modification did not provoke significant changes in the porous texture of the original NH₂-Ti-MOFs.

The UV-Vis spectra of NH₂-Ti-MOFs reveal two prominent absorption bands with maxima at 217 and 370 nm, which are caused by the Ti−O and ligand cluster transition. Furthermore, an absorption band extending...
up to 500 nm can be observed due to the NH$_2$-BDC ligand [30]. After incorporating transition metals into Ti-MOFs, the UV-Vis absorption band redshifted, and the visible region expanded noticeably (Fig. 3(a)). The bandgap energy of all obtained samples was calculated using the graph of $(h\nu)^2$ versus photon energy (h) shown in Fig. 3(b). The bandgap of NH$_2$-Ti-MOFs and 15% Cu/Ti-MOFs were calculated from the absorption line intersection and are 2.56 and 2.42 eV, respectively.

**Photocatalytic Test**

The photocatalyst efficiency of the as-prepared samples was figured out via the degradation of Rhodamine B (RhB) dye under visible light irradiation (Fig. 4(a)). It was found that the rate of degradation of NH$_2$-Ti-MOFs was prolonged after 120 min of irradiation. However, the degradation process significantly rose when doping Cu$^{2+}$ ions into the NH$_2$-Ti-MOFs. Therefore, it is indicated that the Cu$^{2+}$ ion helped the bandgap energy to narrow, which boosted the photocatalyst effect. Furthermore, as per the literature, •OH radicals were generated and acted as electron acceptors, which is the main factor in helping the MOFs generate more holes and encourage the photocatalysis process.

The kinetics of RhB degradation on NH$_2$-Ti-MOFs and bimetallic 15% Cu/Ti-MOFs were also described via the pseudo-first-order (Fig. 4(b)). For 15% Cu/Ti-MOFs, the correlation coefficient ($R^2$) and the rate constant ($k_1$) for the pseudo-first-order kinetic model were the highest. Notably, the kinetic rate of 15% Cu/Ti-MOFs reached 10.23 ($10^{-3}$ min$^{-1}$), which showed the highest photocatalytic performance. The UV-Vis absorption spectra of RhB to irradiation time over Ti-MOFs and 15% Cu/Ti-MOFs are also depicted in Fig. 4(c-d). The RhB dye solution's absorption peak was at 554 nm, and it gradually decreased due to dye degradation, reaching its lowest value at 120 min. The photocatalyst cleavage of the aromatic ring of the dye molecules is thought to cause a decrease in absorption peaks, which leads to the decomposition of the RhB dye [31].

The pH of the solution had a significant impact on the efficiency of the photocatalytic reactions (Fig. 5(a)). The free radicals attacked the dye molecules and caused them to degrade over time. Because of the electrostatic interaction between the negatively charged material surface (from the proton separation process) and the predominant positively charged dye cation at pH 2, the

Fig 5. The effect of pH solution (a) and photocatalyst mechanism of 15% Cu/Ti-MOFs (b).

the photochemical degradation efficiency increased sharply, resulting in a sharp increase in absorbance as well as causing the photochemical reaction. When the pH rises above 8, RhB is deprotonated, and its zwitterion is formed. Furthermore, photochemical degradation was inhibited because the hydroxyl ions competed with the RhB molecules for adsorption on the catalyst surface. This finding is consistent with the findings of Zhao et al. [32]. Reactive radicals (•OH, O₂•−, h⁺) are produced during the irradiation process and are responsible for...
dye degradation. Trapping experiments were used to determine which radical was dominant. According to Fig. 5(b), the final degradation efficiency changed almost noticeably after 2 h of visible light irradiation when added with 1 mM TBA and 1 mM EDTA−2Na. Hence, ‘OH and h’ were predominantly responsible for RhB degradation.

To investigate the stability of the photocatalyst, recycling experiments of 15% Cu/Ti-MOFs were performed under the same conditions. Fig. 6(a) depicts the photodegradation of RhB after three runs. The removal of RhB decreased from 72.62% to 66.05%, indicating that the catalyst can be used repeatedly with no discernible variation in photocatalytic performance. The FTIR spectra (Fig. 6(b)) of fresh and used catalyst (used three-times) proved the stability of 15% Cu/Ti−MOFs after the 3rd -run. The organic linkers C−C and N−H bonds bending vibrations were visible in the FTIR spectra of 15% Cu/Ti−MOFs, with peaks at 1500 and 1620 cm−1, respectively [33-34]. Furthermore, the peaks at 1245 and 1414 cm−1 are associated with a Ti−O framework's bending and symmetric stretching [35]. According to this study, the organic linker's –COOH group was directly attached to the Ti-oxo cluster.

■ CONCLUSION

NH2-Ti-MOFs and 15% Cu/Ti-MOFs were successfully prepared via the solvothermal method and were used to degrade RhB dye efficiently. Compared to the individual Ti-MOFs, 15% Cu/Ti-MOFs exhibited enhanced photocatalytic activity for RhB degradation. The promoted electron transfer by the Cu2+/Cu+ and Ti4+/Ti3+ redox cycles and the efficient separation of photo-excited electron-hole pairs by introducing H2O2 can be attributed to the accelerated photocatalytic degradation of RhB. The prepared 15% Cu/Ti-MOFs also demonstrated good reusability and stability. Further investigation revealed that the principal active species in the degradation process were hydroxyl radicals and holes. The 15% as-synthesized Cu/Ti-MOFs showed promise in the removal of organic contaminants from wastewater.
